EPA Region 5 Records Ctr. 279474

Ms. Gwendolyn Massenburg Remedial Project Manager U.S. Environmental Protection Agency Region 5 77 West Jackson Boulevard Chicago, IL 60604

Subject:

Cost Estimate

Chemical Recovery System Site

142 Locust Street

Elyria, OH

Dear Ms. Massenburg:

T N & Associates, Inc. (TN&A), a member of the STN Environmental Joint Venture with Sullivan International Group, Inc., has prepared these cost estimates in accordance with the requirements of U.S. Environmental Protection Agency (U.S. EPA) Technical Direction Document (TDD) No. S05-0701-001 Chemical Recovery System Site, Elyria, Ohio. TN&A's cost estimates are provided in Attachment A.

TN&A appreciates this opportunity to provide these comments. Should you have any questions or comments, please contact me at 312/220-7000.

Sincerely,

Raghu Nagam Project Manager

Attachment A - TN&A Cost Estimates

OVERVIEW OF REMEDIATION OPTIONS CHEMICAL RECOVERY SYSTEM SITE ELYRIA, OHIO

START contractor STN JV evaluated two soil remediation alternatives for the Chemical Recovery System (CRS) site located in Elyria, OH. These alternatives are:

- 1. Soil Vapor Extraction (SVE)
- 2. Soil Excavation and off-site Disposal

SVE Alternative:

The soil vapor extraction (SVE) alternative involves applying vacuum through extraction wells spread over the 0.5 acre area and recovering the soil vapors containing volatile contaminants. Vertical extraction wells at the CRS site could typically be from depths of 5 feet to 10 feet below ground surface (bgs). It is assumed that the volatile organic compounds (VOCs) collected through SVE system would have very low trichloroethylene (TCE) concentrations and can be discharged to the atmosphere without any treatment. Under ideal conditions, a SVE system can attain a maximum efficiency of 90%. Some of the key factors that determine the efficiency of an SVE system include:

- 1. Preferential pathways for air migration
- 2. Pressure drop
- 3. Area available for SVE

SVE EVALUATION:

In the proposed SVE remediation area, TCE concentrations ranged from 450 milligrams per kilogram (mg/kg) to 120 mg/Kg in the 0 to 4 ft bgs sample. The highest TCE concentration of 450 mg/kg was encountered in the 2-4 ft bgs depth sample of GP-37 location. A TCE concentration of 16 mg/Kg was observed in the 8 ft bgs sample. In the SVE area, higher TCE concentrations were encountered in the top 4 feet of the soil.

In general, fill material was typically encountered in the top 4 feet of the 0.5 acre area evaluated for SVE remediation. In some areas (GP-37), fill material with medium sand was observed up to a depth of 3.5 ft bgs followed by fine to medium sand up to a depth of 5.5 ft bgs. Refusal was encountered at a depth of 5.5 ft bgs in the GP-37 area. The GP-40 soil boring log indicated fill material with sandy clay in the 0-4 feet bgs interval and sandy clay up to 12 ft bgs. Groundwater was encountered at 12 ft bgs. The GP-39

soil boring log indicated fill material with medium sand, coal, glass and brick up to 8 ft bgs, moist soil with silty sand up to 11.5 ft bgs and refusal at a depth of 11.5 ft bgs. Soil boring logs shown in the remedial investigation report prepared by Parsons Engineering indicated refusal at less than 10 ft bgs in a majority of sample locations.

For SVE system to function efficiently, vertical extraction wells are typically used at depths of 1.5 meters (5 feet) or greater. Since most of the contamination is predominantly in the top 4 feet and located in fill, sand, and clay matrix, preferential pathways are likely to occur in the SVE area. Preferential pathways allow air to migrate predominantly through these preferred pathways and remove volatiles in and around these pathways only. This results in a reduced SVE efficiency. After the contamination in the preferential pathways is reduced, the SVE system would have to be shut down until contamination from other areas migrate in to the preferential pathways. This will prolong the time period of SVE system.

The fill material typically has voids that are detrimental to maintaining a constant pressure. A constant pressure is essential for effective SVE operations. Fill material in the proposed SVE area may lead to significant pressure drops thus drastically reducing the vacuum capabilities and vapor extraction efficiency.

In a typical SVE process, induced vacuum results in the upwelling (rise) of the groundwater table and reduction in the available treatment area. With the depth to bedrock ranging from 5 to 12 feet in the proposed SVE area and the close proximity to the river, increase in precipitation events and flooding from the river would create a perched aquifer thus reducing the actual area available for SVE remediation. This condition coupled with upwelling of the water table because of induced vacuum would decrease the area of SVE remediation and decrease SVE efficiency. The shallow bedrock and the close proximity of the river to the site would require additional measures to reduce the quantity of water drawn in to the SVE system. In spite of this, considerable quantity of water may find its way in to the SVE system requiring treatment and disposal per state and federal applicable standards.

One of the disadvantages of SVE system is that concentration reductions greater than 90% are difficult to achieve. The highest TCE concentration of 450 mg/kg encountered at the site would undergo a reduction of 405 mg/kg and still leave behind a concentration of 24 mg/kg. The site cleanup goal of 0.11 mg/kg will not be achievable with SVE system. A 90% reduction in the average TCE concentration of 102 mg/kg in the 0.5 acre area will result in TCE concentration of 10.22 mg/kg in the remainder of the soil. An 80% TCE concentration reduction would result in 20.44 mg/kg while a 70% concentration reduction would

result in 30.66 mg/kg concentration of TCE in the remainder of the soil at the site. Because of shallow bedrock conditions, perched groundwater, and fill and clay material at the site, the ideal efficiency of 90% would not be attainable at the CRS site.

EXCAVATION ALTERNATIVE

The Excavation Alternative involves excavating the 0.5-acre section of the CRS site up to an average depth of 6 ft bgs. This average depth is based on the assumption that some areas may require excavation up to 4 ft while other areas require excavation up to 6-8ft bgs. This action will remove high concentrations of TCE in soil up to the bed rock in some sections of the 0.5 acre area. The highest TCE concentration of 450 mg/kg was encountered within the top 6 ft of the soil. After removing this contamination at the 6 ft bgs area, the highest concentration remaining at the site would be 16 mg/kg. After addressing the contamination at the 8 ft bgs area, the highest concentration remaining in the 0.5-acre area would be 0.99 mg/kg. The alternative also includes backfilling the excavated area with clean soil and installing a 2-foot soil cover over the rest of the site area. The excavation alternative provides a reliable alternative and removes immediate threat to human health and the environment through direct contact and through potential leaching in to the groundwater from the 0.5 acre area at the CRS site.

CONCLUSIONS

The SVE alternative, because of site conditions discussed above, may not be able to remove TCE concentrations effectively and in a reasonable time period to meet the desired project objective of abating direct contact threat and reducing the TCE concentration to 0.11 mg/Kg. Excavation alternative offers a one-time remedy where site contamination up to 8 ft bgs could be removed, leaving a maximum residual contamination up to 0.99 mg/Kg in the soil. The Excavation alternative also abates the direct contact threat once the remedy is completed and minimizes further leaching and reduced the time frame for natural attenuation.

Monitoring Well Network Cost Estimates Chemical Recovery System Elvria, Ohio

Cost estimates were developed for vertical profiling at 7 potential shallow and deep monitoring well locations and installing 11 monitoring wells. These activities were assumed to be conducted in four phases. Phase 1 and phase 2 involve well profiling and monitoring well installation on the site and phase 3 and phase 4 involve well profiling and monitoring well installation outside the site boundaries. The estimated cost of \$298,612 is based on quotes obtained from the drillers.

Phase 1

Phase 1 involves vertical profiling four potential monitoring well locations using water rotary drilling techniques. Chemical analysis samples for trichloroethylene (TCE) contamination would be collected from five-foot intervals and analyzed at a commercial laboratory.

Phase 2

After evaluating the results of phase 1, five monitoring wells will be installed within the site boundaries. Because some of the monitoring wells have to be installed in the bedrock, water rotary drilling technique would be the most viable method of installing the wells at the site.

Phase 3

Phase 3 involves vertical profiling of four locations just outside the site boundary and across the river as shown in Figure 3-10. However, due to the terrain and local conditions in the site area, a drill rig may encounter mobilization problems. Such locations may have to be relocated based on drill rig accessibility. Similar to phase 1, chemical analysis samples will be collected and analyzed during phase 3 activities.

Phase 4

Six monitoring wells will be installed in phase 4 based on phase 3 evaluation. These wells will be installed using the water rotary drill technique.

These cost estimates could be further streamlined, if work activities can be conducted in two phases instead of four phases. This will reduce 2 mobilizations and demobilizations and associated cost and time.

Under this streamlined approach, vertical profiling and monitoring well installation on the site itself would occur during first mobilization and outside the site boundaries would occur during the second mobilization. Samples will be analyzed within a 24-hour time period of each vertical profiling well sampling. While waiting for the chemical results of one location, vertical profiling at the next location would occur. Monitoring wells will be installed either after completing well profiling of all wells are between vertical profiling of individual wells.

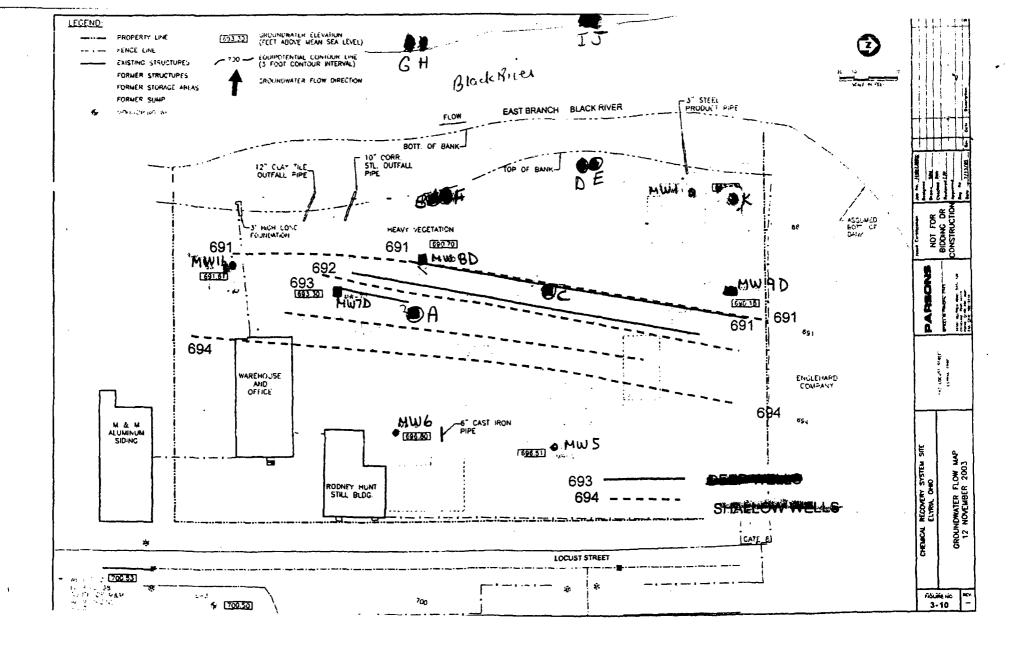

CHEMICAL RECOVERY SYSTEM SITE ELYRIA, LORAINE COUNTY, OHIO

Assumptions

- 1. Labor costs are based on Davis-bacon act wages
- 2. Chemical analysis costs for vertical profilng samples are based on a 24-hour turnaround time
- 3. Driling quote used here was obtained from Geo Services, Inc of Illinois for water rotary drilling
- 4. During vertical profiling, soil samples were assumed to be collected from 5-foot intervals and analyzed for TCE Cost estimates prepared by STN Environmental, JV, under START contract EP-S5-06-03 and TDD number S05-0701-001

Chemical Recovery Systems, Inc Proposed Remedy Conference Call

Monday, March 5, 2007 2:00 to 3:00 PM (Central)

Phone number: 1.866.299.3188 - Conference Code: 3123531289#
